

General instructions:

- For values to be excluded, it is specified whether extreme/mild outliers or below/above which value to exclude them.
- In very few cases, the numbers made no sense (even if rescaled) so the species was excluded completely, with an explanation in the comments column.
- For some species which had more than one species graph, it is specified from which graph to keep the values.
- In many cases, it was evident that the values came from two databases, with one on the correct scale and the other not. In that case, it is specified which values to be rescaled.

Diaspore mass: I was mostly checking if it fits in the family range and in case of doubts, I would search the mass of the taxon on: <https://floraveg.eu/taxon/>.

Nitrogen content per unit mass: Values for this trait usually range between 10 to 30 (maximum 40-50) mg/g, so based on that I was adjusting the scale or excluding values.

Stem specific density: I was mostly checking if the species fits into a certain range:

- angiosperm trees and shrubs 0.6-1.2 g/cm³
- gymnosperms 0.3-0.7
- herbaceous plants 0.1-0.5

and based on that adjusting the scale or excluding some values.

Height: no specific details

Leaf area: As this trait is probably the most variable between but also within species, the range of values is often wider than for other traits. I used <https://thetmeasureofthings.com/> to visualise more easily the size of leaves.
